ABSTRACT

Objective: to assess the risks of development of hormone-related tumours in transsexuals receiving treatment with cross-sex hormones
Design: description of cases of transsexuals who have developed a hormone-related malignancy observed in the own clinic or reported in the literature. Recommendations for early diagnosis and prevention are presented.
Methods. Review of the literature in Pubmed.
Results: in male-to-female transsexuals receiving estrogen administration lactotroph adenomas, breast cancer and prostate cancer have been reported. In female-to-male transsexuals receiving treatment with testosterone a single case of breast carcinoma and several cases of ovarian cancer have been reported. So far endometrial cancer has not been encountered though it remains a potential malignant development.
Conclusions: there are so far only a few cases of hormone-related cancer in transsexuals. There may be an underreporting. The probability of a hormone-related tumor increases with duration of exposure to cross-sex hormones and the aging of the population of transsexuals
For transsexuals the acquisition of the secondary sex characteristics of the other
gender is fundamental to sex reassignment. Acquisition of these secondary sex
characteristics is contingent on sex steroids. There are presently no indications that
there are fundamental sex differences in sensitivity to hormone action of sex steroids.
Nearly all hormone-related biochemical processes can be sex-reversed by the
administration of cross-sex hormones.

The typical transsexual requesting treatment is a young to middle-aged and healthy
person and, therefore, there are usually no or few absolute or relative
contraindications against cross-sex hormone administration.

After reassignment surgery, which includes gonadectomy, hormone therapy must be
continued. It is reasonable to assume that the principles of treatment are similar to
those of other subjects without own gonadal hormonal secretion. An unresolved
question is whether in the long-term the administration of cross-sex hormones is safe,
at least as safe as administration of sex steroids to a subject receiving long-term sex-
appropriate sex steroids. While the initial treatment with cross-sex hormones is
mainly concentrated in specialized centers, complications occurring in the longer-
term are often seen in general practice, and these complications are only occasionally
reported in the scientific literature. So, it is likely that that there is an underreporting
of (serious) complications of cross-sex hormone therapy. The authors have been
contacted by other physicians with regard to medical occurrences in transsexuals, but
these cases are often lost for follow-up and registration/reporting of (potential)
complications of cross-sex hormonal treatment does not materialize. The latter
situation prevents a fair comparison with epidemiological data in the general
population. Recently, a website has been opened for reporting side effects of cross-
sex hormone treatment: http://www.wpath.org/resources_transgender.cfm, click
under transgender information: resource links.

This contribution focuses on the risks of development of hormone –dependent
malignancies in transsexuals. It will try to formulate some recommendations to
reduce the risk of development of hormone-related malignancies and strategies which
might lead to early diagnosis.
In this regard there are a number of considerations.

There are no evidence-based recommendations for optimal hormonal treatment regimens for transsexuals but there are a number of expert opinions in the literature. As yet there are no recommendations as to what age cross-sex hormone administration must be continued. Should, for instance, estrogen administration to male-to-female transsexuals (MTF) follow the guidelines formulated for postmenopausal women and should the administration of estrogens be discontinued at a certain age? MTF themselves are usually reluctant to stop administration of hormones for fear that the secondary sex characteristics of the acquired sex will diminish. And there is presently no evidence-based recommendation to make on risks/benefits of continuing/stopping hormones. The duration of sex steroid administration is probably an element in the risk of development of hormone-related malignancies.

Health insurance policies vary with regard to their coverage of medical expenses related to sex-reassignment treatment. Broadly speaking, most transsexuals in Western Europe undergo sex-reassignment surgery within a timeframe of 2-3 years after initiation of cross-sex hormones. In other parts of the world transsexuals, for financial or other reasons, are not operated within this timeframe. Long-term exposure of their gonads/genitalia and breasts to cross-sex hormones may involve greater risk of development of malignancies.

While this should not be generalized to the entire population of transsexuals, part of the population, particularly those that receive their cross-sex hormones outside of official medicine, use abnormally high doses of cross-sex hormones with a potential impact on the development of malignancies.

CROSS-SEX HORMONES AND HORMONE-DEPENDENT TUMORS

Some cancers (of reproductive organs) are hormone related. The biology of hormone-dependent tumors differs from tissue to tissue. The Women's Health Initiative Study has recently demonstrated that women receiving estrogen plus progestin (HRT) have an increased risk of invasive breast carcinoma, but women receiving estrogen only (estrogen replacement therapy) exhibit no increased risk of breast carcinoma. By contrast, the risk of endometrial carcinoma increases with estrogen replacement
therapy, while HRT reduces the risk of endometrial carcinoma. These clinical findings suggest that the biological roles of estrogen and progestin in tumour development are different between the endometrium and breast, even though both are considered as "estrogen-dependent tissues". This discrepancy might be explained by the different roles of enzymes involved in the formation of active sex steroids in these tissues. The concentration of these enzymes is dissimilar between endometrial and breast carcinoma resulting in different effects of estrogens and progestins in tumour development in these tissues.

Overall, so far not many hormone-dependent tumors have been reported in hormonally treated female-to-male transsexuals (FTM) and they seem a rare occurrence in MTF. The first documented hormone treatments of transsexuals started in the 1970-ies and the length of time of exposure to hormones may have been too short for tumors to manifest themselves. In addition, transsexualism is a rare phenomenon (the highest estimates are 1:12,000 males and 1:30,000 females). Moreover, the prevalence of hormone-dependent tumors is low, and this may lead to an underestimation of tumors since most clinicians will only encounter single cases which are less likely to be reported in the literature than larger numbers. Therefore, the conclusion that hormone-related tumors are not highly prevalent among the transsexual population must be drawn with great caution.

MTF, as a rule, use higher doses of estrogens than women lacking production of gonadal hormones. Compared to hypogonadal women, exposure of transsexuals to estrogens used to be over a shorter period of lifetime, since transsexuals mostly start cross-sex hormone treatment well after puberty, though this is changing. Presently, adolescent transsexuals may be eligible for cross-sex hormone treatment. Further, transsexuals beyond the ages of 50 or 60 years, have a strong inclination to continue cross-sex hormones increasing their period of time of exposure to sex steroids. The following is a summary of reports in the literature on tumors in transsexuals, and some recommendations are given on caveats, possible prevention and early diagnosis.

*Lactotroph adenoma*

Several cases of lactotroph adenoma (prolactinoma) following high dose estrogen administration have been reported in patients with normal serum prolactin...
concentrations before therapy. The Amsterdam gender clinic recently encountered a case of development of a pituitary microprolactinoma in a MTF, only occurring after 14 years of normal-dosed estrogen treatment. Though causality has not been established, we recommend that serum prolactin levels continue to be monitored in estrogen-treated MTF in the long-term.

Breast cancer

There are two reports of MTF who developed breast carcinomas while receiving estrogen treatment. Breast fibroadenomas in MTF receiving hormonal treatment have been observed. In the Amsterdam gender clinic no single case of breast cancer has been observed in a series of approximately 2200 MTF, cumulative over 30 years, but recently one case has been diagnosed. On the basis of the above information one would be inclined to think that breast carcinomas in MTF are rare. But it has to be kept in mind that follow-up of 2200 subjects, with a strong variation in estrogen exposure (from 1 to 25 years), do not allow firm conclusions as to assessing risks. Aging is a factor in the development of cancer, and prolonged exposure to estrogens may also prove to be a factor. Indeed, the risk of developing breast cancer is strongly associated with exposure to estrogens in women and hence the use of anti-estrogens as an endocrine treatment option in breast cancer. However, there is only a slight indication of increased oestrogen receptor levels in non-neoplastic tissue in breast cancer cases. Moreover, the expression of these hormone receptors do not always imply a response to treatment with ant-oestrogens. and patients who experience response at first may become resistant after prolonged treatment. It might well be that tissue specific hormone actions and local hormone concentrations are more relevant than hormonal levels in the peripheral circulation. Nowadays, local enzymes involved in the formation of active sex steroids in the tissue itself are believed to play a major role in cancer formation. The class of 17beta-hydroxysteroid dehydrogenases (17-HSDs) are enzymes involved in the formation of active sex steroids locally in the tissues itself upon estrogen replacement therapy (Ito, 2007). An other enzyme is the aromatase, also involved in local estrogen synthesis in the peripheral tissues. Recently this enzyme has also been studied as a possible target enzyme of endocrine treatment regimes and the use of aromatase inhibitors was successful in large clinical studies and is now commonly used in women with breast cancer.
cancer. As stated above estrogen alone treatment exhibit no increased risk of breast carcinoma and is believed to be safer than combined estrogen plus progestin therapy.

The discussion as to the age at which estrogen treatment in MTF should be terminated is pertinent but has not been.

There is a higher risk of developing breast carcinoma in men who carry germline mutations in the BRCA2 gene than men in the general population. Mutations in the BRCA1 gene may also constitute a higher risk for breast carcinoma. These risk factors also apply to women, so, upon taking a medical history, it is recommended to enquire about familial occurrence of breast carcinomas. In any case, in addition to regular medical examination, breast self-examination must be part of the monitoring of estrogen administration, following the same guidelines that exist for other women, with a clinical examinations every year or twice a year and self-examinations every month. The guidelines for mammography differ from country to country and therefore, a general recommendation is very difficult to make, but an examination every 12 to 24 month if the initial examination shows no abnormalities, seems reasonable.

Amazingly, breast cancer has been reported in a FTM after bilateral subcutaneous mastectomy while receiving treatment with testosterone. This occurred in postoperative residual mammary tissue after 10 years of treatment with testosterone, which is partially aromatized to estradiol. The issue of the role of androgens in female breast cancer has not been conclusively resolved. Some authors have described androgens as a risk factor, others view it as protective against cancer development. It is the position of the North American Menopause Society that there are no randomized controlled trials of sufficient size and duration to evaluate the effect of testosterone treatment on breast cancer risk in postmenopausal or menopausal women. Testosterone enanthate has been approved in both the United States and Canada for the treatment of metastatic breast cancer in the 1950s.

It is of note that androgens (both endogenous and administered are partially aromatized to estradiol, so FTM receiving testosterone administration have still substantial levels of circulating estrogens. As a consequence, in FTM who have not undergone mastectomy, clinicians should be aware of the potential of development of a breast carcinoma.
Benign prostate hyperplasia and prostate cancer

The prostate is not removed with sex reassignment surgery. Prostatectomy is a surgically cumbersome operation, with possible complications, such as urinary incontinence. As expected, the prostate volume shrinks after androgen deprivation. Estrogen exposure does not induce signs of hyperplasia or (pre)malignancy. Two cases of benign prostate hyperplasia, requiring transurethral prostate resection, have been described in subjects who had been orchidectomized and had been treated with estrogens-only for more than 20 years. Another case of squamous metaplasia of the verumontanum has been reported leading to obstruction due to hypertrophy. Three cases of prostate cancer in MTF taking estrogen have been reported. It is not clear whether these cancers were estrogen-sensitive, or whether they were present prior to beginning estrogen administration and then subsequently de-differentiated to become androgen-independent. These patients were each over 50 years of age when they started cross-sex hormone treatment (with total androgen ablation).

Epidemiological studies have shown that orchidectomy before age 40 prevents the development of prostate cancer and benign prostate hyperplasia, and the above cases do not contradict this notion. In most clinics, screening for the development of levels of prostate specific antigen is not routinely done. The question could be raised whether a digital rectal examination of the prostate in combination with measuring prostate specific antigen should be recommended in the follow-up of MTF transsexuals. A recent study in Germany indicated that the age-standardized incidence rate was 115/100,000 men per year, and the median age at diagnosis was 70 years. The three reported cases of prostate cancers in an unknown number of MTF set against this incidence do not lead to a evidence-based recommendation on routine testing. The three reported cases of prostate cancer were all in subjects who started cross-sex hormones late in life. So, maybe measurement of prostate specific antigen may be limited to candidates with a late start of hormone treatment or those who have a family history of prostate cancer. Obviously, health economics are a factor in how comprehensive laboratory monitoring of a population will be.

Ovarian cancer
Ovariectomy is recommended in FTM when they are eligible for surgical sex reassignment, usually taking place 18-24 months after start of testosterone administration. Three cases of ovarian carcinoma in testosterone-treated FTM, diagnosed before they underwent surgery, have been reported\textsuperscript{32,33}. It has been described that the ovaries of FTM taking androgens resemble polycystic ovaries\textsuperscript{34}, but observations in the clinic of one of the authors (AM) are not confirmatory. The earlier notion that polycystic degenerated ovaries are more prone to develop cancer appears not tenable. But there is an upregulation of androgen receptors in ovarian and uterine tissue in long-term treated FTM\textsuperscript{35}.

**Endometrial cancer**

To our knowledge endometrial cancer has not been reported in FTM, but it remains a risk in FTM who have not been operated in the longer-term. As indicated above, testosterone is partially aromatized to estradiol and the endometrium is exposed to unopposed action of estrogens. Unopposed estrogen action substantially increases the risk of endometrial carcinoma. Risks of unopposed estrogen action remain elevated long after actual use has been terminated.

In vitro studies have shown a direct effect of androgens on endometrial function by demonstrating the presence of androgen receptors in cultured endometrial epithelial cells\textsuperscript{36}.

The local availability of androgens and the finding that aromatase activity is present in both endometrial cancer and benign endometrial tissue support the hypothesis that aromatase activity in the endometrium may play a role in malignant transformation by converting androgens into mitogenic estrogens in the endometrial tissue\textsuperscript{37}. In women using continuous estrogen and testosterone regimes a greater incidence of simple, low-grade endometrial hyperplasia was found than in women using continuous estrogen and progestin regimes\textsuperscript{38}. However, during short-term treatment with testosterone in postmenopausal women there was no stimulation of endometrial proliferation. In addition, testosterone appeared to counteract endometrial proliferation induced by estrogen to a certain extent\textsuperscript{39}. It has been reported that testosterone is involved in the regulation of estrogen and progestin receptor expression in the endometrium which was decreased in glands after combined treatment with estradiol and testosterone\textsuperscript{40}. Testosterone administration to
postmenopausal women resulting in physiological to slightly supraphysiological serum-free testosterone levels appeared to be safe for a period of at least 2 years\textsuperscript{41}. Recently it was shown that intermittent progesterone administration to women using continuous estrogen administration, is, contrary to earlier beliefs, associated with an increased risk of endometrial cancer\textsuperscript{42}. Therefore estrogen and continuous progestin is now recommended as menopausal hormone therapy in women who have not had a hysterectomy\textsuperscript{43}.

Testosterone administration to FTM usually leads to no or a small decline in plasma estradiol levels\textsuperscript{34, 44}. Since part of testosterone is aromatized to estradiol, plasma levels remain in a such range that biological effects can be expected\textsuperscript{34, 44}. Consequently, testosterone treatment in FTM generates biologically active levels of estradiol (proportional to the circulating levels of testosterone and sometimes higher than in postmenopausal women receiving estrogen treatment) which are not opposed by progesterone action. In FTM whose uterus has not surgically been removed, addition of a progestin might, therefore, be a consideration.

For surveillance, a once a year transvaginal, transrectal or transabdominal ultrasound examination is recommended if there are no bleedings. Only when there is a bleeding during testosterone treatment we perform additional examinations.

\textit{Tumours of non-reproductive organs and sex steroids}

A number of tumours shows sex differences in their prevalence and it is reasonable to assume that sex steroids might be one of the factors to explain this sex difference. This applies to tumours of the lung (adenocarcinoma, small cell carcinoma)\textsuperscript{45}, of the colon\textsuperscript{46}, of the bladder (but the latter mainly in animal models), and of the brain, particularly meningeomas\textsuperscript{47}. These tumours have been observed in transsexuals but not in numbers that raise suspicion that cross-sex hormone treatment has been a significant factor in the development.

\textit{In summary:}

Malignancies related to cross-sex hormone treatment of transsexuals have so far, fortunately, been a rare occurrence. But, theoretically, there a valid reasons to expect a higher incidence in the future. Cross-sex hormone administration is of relatively
recent date in medicine. Most transsexuals undergo treatment well before middle age and part of the population starts to age now which implies exposure to hormones over more than three or four decades. Further, while usually cross-hormone treatment is initiated in specialized center, for the longer-term transsexuals are inclined to consult in more conveniently located general clinics where physicians are less familiar with the condition and the awareness of potential complications, such as malignancies might be lower.
