Abstract (Limit = 250, Current = 249)

**Background:** Spontaneous remission is rare in ectopic ACTH syndrome (EAS).

**Objective:** We describe four patients with presumed EAS in whom long-term treatment with steroidogenesis inhibitors was followed by prolonged remission of hypercortisolemia.

**Results:** Biochemical testing was consistent with EAS but imaging failed to identify a tumor. Patients were treated with ketoconazole alone or with mitotane and/or metyrapone to control hypercortisolemia. Dexamethasone was added when a block and replace strategy was used. Treatment with steroidogenesis inhibitors for 3-10 years in these patients was followed by a prolonged period of remission (15-60 months). During remission, the first patient had an elevated ACTH, low cortisol and 24-hour urine cortisol (UFC), and adrenal atrophy on CT scan during remission, suggesting a direct toxic effect on the adrenal glands. Cases 2 and 3 had normal to low ACTH levels and low normal UFC consistent with an effect at the level of the ectopic tumor. They did not have a history of cyclicity and case 3 has been in remission for ~5 years making cyclic Cushing’s syndrome less likely. Case 4, with a history of cyclic hypercortisolism, had normal to slightly elevated ACTH levels and low normal UFC during remission. The most likely etiology of remission is cyclic production of ACTH by the ectopic tumor.

**Conclusion:** Spontaneous and sustained remission of hypercortisolemia is possible in EAS after long-term treatment with steroidogenesis inhibitors; a drug holiday may be warranted during chronic therapy to evaluate for this. The pathophysiology remains unclear but may involve several different mechanisms.
**Introduction**

Spontaneous remission in Cushing’s syndrome is rare; most cases probably represent infarction of an adrenocorticotropin hormone (ACTH)-secreting pituitary adenoma (1-4). Transient resolution of hypercortisolism, with inter-cyclic periods as long as 4 years, is most common in Cushing’s disease (5-6). Few cases of sustained spontaneous remission have been documented in ectopic ACTH syndrome (EAS) (7-8). Here we describe four cases of presumed EAS where a prolonged remission followed long-term treatment with steroidogenesis inhibitors. Our aim is to make readers aware of this possibility and urge them to assess intermittently for remission in patients receiving chronic treatment with these agents.

**Methods**

All patients had confirmation of Cushing’s syndrome and evaluation of its etiology at the initial National Institutes of Health (NIH) visit after discontinuing any steroidogenesis inhibitors for six weeks or more. Biochemical testing including corticotropin-releasing hormone (CRH) stimulation test, 8 mg dexamethasone suppression test (DST) and inferior petrosal sinus sampling (IPSS) was consistent with EAS. As previously reported, imaging studies (computerized tomography (CT) and magnetic resonance imaging (MRI) of neck, chest, abdomen, pelvis, and standard 6 mCi dose octreotide scan) performed every 6-12 months failed to identify a source (9, cases 31-34). Some patients received [18F]L-3,4-dihydroxyphenylalanine (F-DOPA) positron emission tomography scans, 64-slice gated cardiac CT, cardiac MRI or an 18 mCi dose octreotide scan (9).

**Case 1**
A 42 year-old man presented in 1999 with weight gain, moon facies, proximal muscle weakness, easy bruising, violaceous striae, and an elevated 24-hour urine cortisol (UFC) and ACTH. IPSS suggested an ectopic source of ACTH. Perhaps because of a 5 mm pituitary mass seen on MRI, the patient underwent hemihypophysectomy at the outside institution but hypercortisolemia persisted and no tumor was seen on pathology. Another institution’s evaluation was consistent with EAS; ketoconazole was initiated when no tumor was found.

At the NIH in 2003, biochemical testing was consistent with EAS and imaging did not identify a source of ectopic ACTH (Table 1). Eucortisolism was achieved initially with ketoconazole, but subsequently he required metyrapone (in 2004) and mitotane (in 2008) to maintain eucortisolism (Figure 1A). After ketoconazole was discontinued because of liver enzyme elevations, UFC, though improved, remained elevated (100–268 mcg/day, 298.1–739.7 nmol/day) and bilateral adrenalectomy was considered.

In June 2009, the patient developed clinical acute adrenal insufficiency; cortisol was 4 mcg/dl (110.4 nmol/liter; normal 5-25 mcg/dl, 138–690 nmol/liter) with a low normal UFC, ACTH was elevated (Table 1) and the adrenal glands were atrophic (Figure 2). Mitotane and metyrapone were discontinued and hydrocortisone was initiated. Over the next 16 months the signs and symptoms of hypercortisolism resolved.

In October 2010, the patient had recurrent symptoms, elevated UFC and ACTH and recurrent adrenal gland hyperplasia. Hydrocortisone was discontinued. Imaging studies failed to localize a source of ectopic ACTH and he underwent bilateral adrenalectomy.

**Case 2**
A 39 year-old man presented with a six-month history of increasing fatigue, apathy, decreasing exercise capacity, weight gain and hypertension. At the NIH biochemical testing and IPSS suggested EAS. Surgical resection of a right lower lung lesion seen on imaging studies was unsuccessful (Table 1). Treatment with ketoconazole and metyrapone was started (Figure 1B); metyrapone was later discontinued. On ketoconazole, UFC levels were normal and ACTH levels remained slightly elevated.

In March 2008, the patient discontinued ketoconazole because he wanted to pursue a “natural” way of life without taking any medications. One year later, off all medical therapy, he reported resolution of signs and symptoms of hypercortisolism except for muscle weakness. Biochemical testing confirmed eucortisolemia (Figure 1B, Table 1). The patient remains off medications, and reported increasing muscle strength with no evidence of recurrence in October 2011.

Case 3

A 56 year-old woman presented in 2002 with truncal obesity, hirsutism, easy bruising, lower extremity swelling, increasing blood pressure, and low bone mineral density. At the NIH in 2003 biochemical testing was suggestive of EAS (Table 1). CT scan showed bilateral adrenal hyperplasia. After imaging studies failed to identify the source of ACTH, ketoconazole was initiated. Metyrapone was later added along with dexamethasone using a “block and replace” strategy (Figure 1C).

In September 2006, the patient had a low ACTH level and an undetectable UFC. CT scan showed atrophic adrenal glands. Steroidogenesis inhibitors were discontinued and she was maintained on dexamethasone 250 mcg daily. In September of 2007, ACTH and UFC were in
the low normal range and the cortisol response to ACTH stimulation was normal; dexamethasone was discontinued. An 8 mm retrocardiac mass was noted on CT and MRI of the chest but was not resected, as the patient was eucortisolemic. ACTH and UFC values remain in the low normal range with no signs and symptoms of hypercortisolism or adrenal insufficiency as of November 2011 (Figure 1C, Table 1).

Case 4

A 41 year-old man was admitted with sudden onset altered mental status, hypertension, and hypokalemia in May of 2001. Biochemical evaluation confirmed the diagnosis of ACTH-dependent Cushing’s syndrome. Imaging studies did not identify a source of ectopic ACTH secretion, but pituitary MRI showed an inferior convexity and asymmetric enlargement of the left side. IPSS suggested a pituitary source of ACTH, but hypercortisolism was not confirmed at the time of IPSS.

Ketoconazole and cyproheptadine were initiated after unsuccessful transsphenoidal surgery (TSS) in October of 2001, and cortisol levels decreased. A repeat IPSS performed off all medications was consistent with a pituitary source of ACTH. However, the patient was not hypercortisolemic at that time [UFC = 2 mcg/day (5.5 nmol/day), ACTH = 3 pg/ml (0.7 pmol/liter)] (Figure 1D). After ~6 months remission, hypercortisolemia and high ACTH levels recurred, consistent with cyclic Cushing’s syndrome. For unclear reasons, the patient underwent a second unsuccessful TSS in July 2003.

The patient was then referred to the NIH. Biochemical testing including IPSS performed during hypercortisolism was consistent with EAS (Table 1). Ketoconazole was restarted after imaging studies failed to identify a source of ectopic ACTH. Over the next few years the patient
was maintained on a block and replace regimen with ketoconazole (400-1000 mg/day),
cyproheptadine 16 mg/day (continued by his local physician) and low dose dexamethasone (125
mcg/day). On this regimen UFC remained undetectable, but ACTH ranged from 15 to 66 pg/ml
(3.3 to 14.5 pmol/liter).

In June of 2009, the patient developed adrenal insufficiency; ketoconazole was
discontinued and dexamethasone increased to 250 mcg daily. This remission persisted for ~ 6
months followed by recurrent hypercortisolism, and ketoconazole was reinitiated.

In June 2010, ACTH was elevated at 60 pg/ml (13.2 pmol/liter) with a UFC of 12
mcg/day (33.1 nmol/day). Repeat testing after discontinuation of ketoconazole confirmed an
elevated ACTH and low normal UFC. The adrenal glands were normal size on CT scan and the
patient did not have symptoms of hypercortisolism or adrenal insufficiency. An ACTH
stimulation test showed borderline peak cortisol response at 17 mcg/dl (469.2 nmol/liter);
dexamethasone was continued. In June 2011 the morning cortisol (3.5 mcg/dl (96.6 nmol/liter))
and UFC were low with a normal ACTH (Table 1). The cortisol response to ACTH stimulation
was normal. Patient has since been maintained on hydrocortisone 10 mg daily and continues to
have no signs and symptoms of recurrence as of October 2011.

Discussion

Spontaneous and sustained remission is rarely reported in EAS (7-8). Beardwell et al.
described two cases (biochemical testing consistent with EAS but a source of ectopic ACTH not
identified) in whom hypercortisolism resolved for up to 14 months after treatment with
metyrapone. One patient had normal ACTH and cortisol levels 6 months after two years
treatment (maximum dose 2250 mg/day). The second patient was in remission for ~14 months
after seven months treatment with metyrapone 3000 mg daily and prednisolone 7.5 mg daily (7). The authors hypothesized that spontaneous remission in these cases resulted from a direct effect of metyrapone on ACTH secretion from the ectopic tumor or that the tumor required high cortisol levels to secrete ACTH.

Loh and colleagues described a case of EAS due to a pheochromocytoma in whom treatment with ketoconazole (400 to 600 mg/day) for five months was followed by spontaneous clinical and biochemical remission for 18 months until resection of the pheochromocytoma (8).

We describe four cases with presumed EAS where long-term treatment with steroidogenesis inhibitors was followed by remission for 15-60 months. The mechanism of remission in these cases remains unclear. We postulate that they represent a direct effect on the adrenal glands (case 1), effects on tumoral ACTH secretion (cases 2 and 3) and cyclic ACTH secretion (case 4).

In the case of the first patient, treatment with steroidogenesis inhibitors for ~10 years was followed by resolution of hypercortisolemia for ~16 months (Table 1). Remission was associated with an elevated ACTH level, low UFC and bilateral adrenal atrophy. There are few data on the long-term effects of combined treatment with ketoconazole and metyrapone on the adrenal glands and/or ACTH secretion by a tumor. Mitotane has an adrenolytic effect when given chronically at high doses (>4 gm/day) and this underlies its use in the treatment of adrenal cancer (10-11). However, the highest daily dose of mitotane used in this patient was 2 grams and the duration of treatment was 1.5 years. Although mitotane levels were not measured, it is likely that mitotane, in combination with long-term treatment with ketoconazole and metyrapone, had a direct toxic effect on the adrenal glands that was reversible after discontinuation of treatment.

In the second case, treatment with ketoconazole for ~6 years was accompanied by gradually decreasing ACTH levels followed by spontaneous resolution of hypercortisolism. Although we
do not have recent biochemical data, the patient reports no signs and symptoms of recurrence and appears to have been in clinical remission for the past three years. At the last biochemical evaluation, after taking no medications for one year, he had a high normal ACTH, normal UFC, and decreasing hyperplasia of the adrenal glands on CT scan. The third patient had a response similar to case 2. In her case, treatment with metyrapone and ketoconazole for more than three years was followed by remission characterized by low ACTH and cortisol levels and bilateral adrenal atrophy. These data are consistent with effects on the tumor to decrease ACTH secretion and/or bioactivity.

As suggested previously, an ACTH-secreting tumor might require high cortisol levels for growth and/or hormone secretion (7). Mizoguchi et al. reported decreasing ACTH and cortisol levels with metyrapone treatment (1500 mg/day for 2 months) in a boy with an ACTH-producing thymic carcinoid tumor. In vitro, tumor cells showed increased proopiomelanocortin (POMC) gene expression when cultured in the presence of 1000 mcg/ml of hydrocortisone (12). In another ACTH-producing thymic carcinoid, ketoconazole treatment (800 mg/day for one week) led to decreased ACTH and cortisol levels. In culture, ketoconazole reduced ACTH secretion from the thymic tumor cells while cortisol and CRH had no effect, suggesting a direct effect on the tumor cells (13). These cases suggest that long-term treatment with ketoconazole and/or metyrapone may decrease tumoral ACTH secretion, either directly or by decreasing hypercortisolemia. It is not known whether these effects are specific to thymic carcinoids or how often they occur.

Another possible explanation for remission may be altered POMC gene expression and defective ACTH production by the ectopic tumor (14-17). The tumor may dedifferentiate or
develop a transcriptional or post-transcriptional defect leading to production of an ACTH molecule with reduced ability to stimulate adrenal hormonogenesis.

At daily doses of 16 to 24 mg, the serotonin receptor antagonist cyproheptadine was associated with decreased ACTH and cortisol levels in Cushing’s disease patients, with reversal of effect upon discontinuation (18-20). However, this finding was not consistent and cyproheptidine is not effective in EAS. Patient 4 was maintained on cyproheptadine by his local physicians. Given the stable dose of cyproheptadine during ACTH fluctuations, it is unlikely that it played a role in inducing remission in this patient.

Case 4 had a history of two previous six-month episodes of remission and currently has been in remission for 15 months. Underlying tumor cyclicity is the most likely explanation and his case illustrates the importance of differentiating sustained remission from cyclic Cushing’s syndrome. Given previous reports of recurrent hypercortisolism in cyclic Cushing’s syndrome even after 4 years (6), the possibility of cyclic production of ACTH in cases 2 and 3 cannot be completely excluded. Like case 2, patient 3 had no history of cyclicity, and has now been in remission for 5 years, making cyclic Cushing’s syndrome less likely.

In conclusion, long-term treatment with steroidogenesis inhibitors was associated with prolonged periods of remission in these four cases with presumed EAS. However, this may not be a causal relationship. The exact pathophysiology of remission in these cases remains unclear and may involve several possible mechanisms that require further study. While surgical resection of the ectopic tumor remains the optimal treatment, medical treatment with steroidogenesis inhibitors can be used when a source of ACTH cannot be identified. Combined therapy with multiple steroidogenesis inhibitors has been shown to be effective in both rapid and chronic control of hypercortisolism (10, 21). However, optimal control of hypercortisolism is of
paramount importance and bilateral adrenalectomy should be considered in cases where this cannot be achieved on medical treatment. Findings from these four cases suggest that ACTH levels should be measured intermittently, or medical therapy should be stopped every one to two years, to assess whether remission has occurred.

**Funding:** This work was supported by the intramural program of the *Eunice Kennedy Shriver* National Institute of Child Health and Human Development, National Institutes of Health.

**Declaration of interest:** The authors declare that there is no conflict of interest that could be perceived as prejudicing the impartiality of the research reported.
